ABSTRACT

Post-harvest losses (PHL) remove a substantial share of the food produced in developing-country agricultural systems, commonly estimated at 20–40 percent for perishables and 10–25 percent for staples, before it reaches a consumer. The dominant policy response has treated PHL as an engineering and logistics problem, funding storage structures, cold chains, and transport upgrades. This paper argues, and constructs a framework to demonstrate, that a large and systematically under-addressed share of post-harvest loss is biological in origin, fungal and mycotoxin contamination, bacterial spoilage and pathogens, pest infestation, and physiological deterioration accelerated by microbial activity, and that the biological layer interacts with the economic layer of the supply chain in ways that standard loss-reduction programming ignores. The paper develops an integrated framework, the Biological Intervention–Supply Chain Economics (BISCE) model, that represents the supply chain as a sequence of loss-generating nodes (harvest, field drying, aggregation, storage, processing, transport, marketing), embeds at each node a biological hazard process with intervention-conditional loss and quality parameters, and embeds at each node an economic decision maker whose adoption of biological interventions (improved drying, hermetic storage, biocontrol agents, sanitation, biological plant-protection treatments, rapid biological diagnostics, cold-chain integration) responds to prices, margins, capital constraints, risk exposure, and the distribution of benefits along the chain. The framework identifies four structural findings: (i) the largest loss-reduction value frequently sits at nodes where the adopting actor has the least private incentive, generating systematic under-investment in early-chain biological interventions; (ii) quality-graded markets convert loss into value and are therefore a precondition for many biological interventions to pay; (iii) aggregation points are the natural leverage sites for surveillance-backed interventions such as hermetic storage and depot-level screening; and (iv) biological and economic interventions are complements, biocontrol and hermetic storage raise returns to each other and to market upgrading, so sequencing matters. The paper applies the framework to three commodity systems (cereal grain, horticulture, and dairy/fish value chains), derives policy instruments that realign incentives along the chain, and closes with an implementation roadmap and research agenda.

Keywords: post-harvest losses; food safety; biological interventions; supply chain economics; hermetic storage; biocontrol; mycotoxins; incentives; developing countries.

DOI: 10.18091/ijsts.v10i4.06

1. INTRODUCTION

1.1 The scale and character of post-harvest loss

The Food and Agriculture Organization's long-standing estimate that roughly one-third of food produced for human consumption is lost or wasted [1], [2], with post-harvest losses in developing countries concentrated between the field and the market, remains among the most cited figures in food policy, and the operational estimates behind it vary by commodity and system: for cereals in sub-Saharan Africa, losses of 10–25 percent across handling and storage are typical; for perishable horticulture, dairy, and fish in warm climates without cold chains, 20–40 percent and above is routinely reported [3]–[7], and experimental economics confirms the cost-effectiveness of loss-reduction investment [8], [9]. Whatever the precise commodity arithmetic, the strategic point is established: in food-deficit regions, reducing post-harvest loss is often the cheapest available form of additional food supply; land, water, and inputs have already been spent on the lost volume, so recovery requires no new production resources, only better handling between harvest and consumption [10], [11]. Environmental health research has begun to apply machine learning and AI frameworks to pollutant exposure and cancer risk [12], [13]. Studies of environmental pollutant exposure, health-risk assessment and AI-based risk prediction in contaminated and recycling settings are reviewed in [12]–[18]. Post-harvest food loss in the US supply chain has been scoped in terms of its factors, impacts and solutions [19].

1.2 The biological core of the problem

What is actually lost? Decomposed, post-harvest loss is overwhelmingly a biological process. Fungal infection, pre-harvest or at storage, destroys grain quality and generates mycotoxins that render food unsafe even where visible loss is modest. Bacterial and fungal spoilage, driven by temperature, moisture, and hygiene, consumes perishables. Insect and rodent infestation destroys stored grain both quantitatively and qualitatively. Physiological deterioration- respiration, sprouting, wilting- is accelerated by the same warm, moist conditions that favor microbes. Each of these processes responds to specific biological interventions: rapid and hygienic drying that interrupts fungal development; hermetic storage that suffocates insects and stabilizes moisture; biological control agents, atoxigenic fungal strains applied competitively against toxigenic *Aspergillus*, antagonistic microbes against storage rots; biological treatments and sanitizers; and, at the diagnostic layer, the rapid detection technologies that identify contamination before it propagates through a lot. The engineering response to PHL- structures, equipment, cold chain- is necessary, but it is the biological process management that determines whether the engineered environment actually preserves safe, marketable food [20], [21].

1.3 The economic mismatch

Why, then, do these interventions not simply diffuse? Because loss reduction is embedded in a supply chain whose actors face different costs, different risk exposures, and different rewards. The farmer who dries grain poorly does so partly because the price system pays the same for moist, moldy grain as for dry, clean grain at the aggregation point; the trader who stores grain in permeable bags does so because hermetic alternatives carry capital and knowledge costs that the margin structure does not reward; the processor who would pay for quality finds no quality-graded market through which to express it. Loss is, in this sense, not merely a technical failure but an equilibrium, the level of biological deterioration that the chain's incentive structure rationally sustains. Interventions that ignore this equilibrium fail in predictable ways: subsidized stores built without drying and hygiene protocols fill with moldy grain; hermetic bags distributed without market differentiation of quality are used once and abandoned; biocontrol programs demonstrate field efficacy and stall at scaling for want of a paying customer at the right node [22] [23]. Retail food loss and waste management has been framed through methods and frameworks for environmental sustainability [24], and marketing standards are shown to drive food loss and waste across the whole supply chain [25].

1.4 Objectives and contribution

This paper constructs the missing integration. It develops the Biological Intervention–Supply Chain Economics (BISCE) framework: a node-structured model in which biological hazard processes and economic decisions are represented jointly, so that the conditions under which biological interventions reduce loss can be analyzed as questions about incentives, margins, and market structure rather than about biology alone. Its objectives are: (i) to review the biological interventions and the loss-reduction evidence; (ii) to formalize the node-structured framework; (iii) to apply it to three contrasting commodity systems; (iv) to derive policy and implementation implications; and (v) to specify the research agenda. The contribution is a shift of diagnostic frame: from "what technology reduces loss" to "what chain structure makes the loss-reducing technology pay, for whom, and at which node [26]."

1.5 Structure

Section 1.6 reviews the biological interventions and the loss literature, and Section 1.7 the loss-assessment evidence. Section 2.1 presents the BISCE framework. Section 2.2 describes calibration methodology, and Section 2.3 the node measurement architecture. Section 3.1 applies the framework to cereals, horticulture, and dairy/fish; Section 3.2 discusses systemic findings; Section 3.3 presents two further systems; Section 3.4 the regional program design; and Section 3.5 the quantitative illustrations. Section 4.1 derives policy instruments, Section 4.2 the financing and institutional design, Section 4.3 program lessons, and Section 4.4 the digitalization frontier. Section 5.1 gives the implementation roadmap and research agenda, and Section 5 concludes.

Recent peer-reviewed evidence on Effects of carboxymethyl cellulose and chitosan bilayer edible coating on postharvest quality of citrus fruit reinforces this assessment [27]–[29].

1.6 Biological post-harvest interventions: a review

1.6.1 Drying, moisture management, and fungal control

Fungal development in grain and perishables is governed principally by water activity and temperature; the single most consequential biological intervention in most staple chains is therefore rapid, uniform drying to safe moisture (typically below 13 percent for cereal grain) and its maintenance. Evidence from storage-insect and aflatoxin-control programs associates improved drying, raised platforms, mechanical and solar dryers, moisture-meter-informed decisions, with reduced mold development, reduced insect multiplication, and lower aflatoxin incidence. Biological control at the fungal layer is led by competitive exclusion: broadcast application of atoxigenic strains of *Aspergillus flavus* displaces toxigenic strains in the field and carries into storage, with field programs in several countries documenting aflatoxin reductions of the order of 70–90 percent in treated volumes under program conditions. Complementary biological sanitation, composting of contaminated cull material, treatment of store surfaces with antagonistic organisms, reduces inoculum carry-over between seasons [5]. Fungal biocontrol agents for postharvest losses of fresh produce have been reviewed [30], and antagonistic microorganisms against postharvest Fusarium have been assessed for mechanisms and efficacy [31].

1.6.2 Hermetic and modified-atmosphere storage

Hermetic storage encloses dry grain in gas-tight containers or liners (bags, cocoons, metal and plastic silos) whose sealed atmosphere, oxygen depleted by respiration, carbon dioxide enriched, kills stored-product insects and suppresses mold metabolism without pesticides. The evidence base is among the strongest in post-harvest technology: controlled trials and program evaluations report insect mortality approaching 100 percent within weeks in properly sealed units, germination and quality maintenance over multi-month storage, and reductions in loss from the double-digit percentages typical of permeable bag storage to low single digits. The technology's constraints are behavioral and economic rather than biological: sealing discipline, proper initial moisture, the capital cost of units, and, critically, the existence of a market that pays for the quality the hermetic system preserves [3]. Grain postharvest technology adopted by smallholder farmers has been examined through a five-pronged strategy [32].

1.6.3 Biological control of spoilage in perishables

Biological control and physical treatments for fresh and minimally processed produce have been reviewed [33]. The mechanisms of antagonistic yeasts on postharvest fruit and vegetables [34], yeast antagonists against postharvest fungal decay in citrus [35], and organic enhancing agents that improve yeast biocontrol [36] extend this evidence. Native yeasts with diverse mechanisms have been tested against postharvest green mold in lemons [37], and yeast cell walls have been proposed as a biocontrol platform for postharvest fruit preservation [38].

For horticulture, the biological toolkit includes antagonistic microbes applied as post-harvest treatments against storage rots (yeasts and bacteria competing with *Botrytis*, *Penicillium*, and colletotrichum-type pathogens), bio-wax and coating formulations carrying antimicrobial compounds, controlled-atmosphere storage that suppresses both host physiology and pathogen development, and biological ripening management. For animal-source foods, biological interventions center on hygiene-based process control, the HACCP logic that assigns critical control points to biological hazards, supplemented by protective cultures in fermented products, biopreservation, and cold-chain-supported suppression of pathogen growth. Across

perishables, the biological interventions are less a discrete technology than a management system: their efficacy is conditioned on temperature and hygiene discipline that the chain's economics must support [39], [40].

1.6.4 Biological diagnostics and surveillance

Detection closes the biological loop: rapid moisture, mold, aflatoxin, and pathogen diagnostics, the lateral-flow, isothermal-amplification, and biosensor platforms reviewed in the companion food-safety literature, allow loss-prone lots to be identified and routed (dried further, treated, diverted to safe uses) before deterioration propagates. Surveillance-backed intervention converts storage from a passive holding operation into a managed biological process, and its deployment economics are analyzed within the framework below [41].

1.6.5 The evidence gap

The review of intervention evidence exposes a pattern that motivates the framework: nearly all intervention studies measure biological efficacy (loss reduction under program conditions); few measure adoption (what share of the chain actually applies the intervention over time); fewer still measure the chain-level economics (who pays, who gains, and whether the incentive structure sustains the intervention). The result is a technology catalog with a scaling graveyard. The BISCE framework is designed to make the economics explicit before deployment, not after.

The supply-chain governance literature, developed principally in energy and infrastructure settings but structurally isomorphic to agricultural chains, supplies the analogues for the framework's decision layer: frameworks and models of supply-chain risk management, resilience, materials readiness, digital governance, predictive procurement planning, national-scale optimization, demurrage elimination and port logistics, asset lifecycle management, IT-systems integration, strategic procurement, contract and vendor governance, regulatory-compliant procurement, secure and scalable chain systems, automation platforms, and ERP–GIS integration [42]–[45].Each maps onto the framework's nodes, procurement and vendor governance onto aggregation, inventory and readiness onto storage, logistics onto transport, and each supports the same lesson: chain performance is governed by the incentive and information structure at each node, not by node technology alone.Cross-sector frameworks for AI and predictive analytics in supply chain management [46] and AI-supported strategic decision-making [47] indicate the analytical direction in which the framework's decision layer can be automated as chain data matures.

1.7 Review of Loss-Assessment Evidence: Magnitudes, Methods, and Attribution

1.7.1 What the loss estimates measure and what they do not

The loss magnitudes cited in Section 1 come from methodologically heterogeneous sources, and the framework's credibility requires stating their limits. Aggregate estimates, the FAO one-third figure and its national descendants, combine measurement protocols from weighing studies, farmer self-reporting, and expert elicitation, with commodity and geography coverage that is systematically uneven: cereals are well studied, perishables are approximated, and the informal-chain segments that dominate developing-country flows are the least measured. The framework's node-structured approach is in part a response to this heterogeneity: it does not need the aggregate to be precise, because its decision analysis runs on node-level, hazard-

specific parameters that are measurable with the instruments of Section 2.2. The policy corollary is worth stating: aggregate loss numbers are advocacy instruments, node-level loss accounts are program-design instruments, and conflating them, designing programs from headline figures, is the documented failure mode of loss-reduction programming [1]–[3], [5].

1.7.2 Magnitude structure by commodity and hazard process

The reviewed assessment literature supports a magnitude structure by commodity class and dominant hazard. In **cereals**, quantitative loss is dominated by insect infestation in storage and spillage in handling, with quality loss (moisture-driven mold, aflatoxin) often exceeding volume loss in value terms, the distinction Section 2.1's loss function formalized, and the reason cereal programs that measure only weight loss understate the problem. In **horticulture**, loss is dominated by mechanical injury and physiological deterioration under ambient temperature, with microbial spoilage secondary but decisive at retail; the loss profile is steeply node-concentrated between harvest and first sale. In **animal-source foods**, volume loss and safety loss are the same event, spoilage is pathogen proliferation, so the health externality and the economic account coincide, and the intervention case is correspondingly the strongest per unit of loss avoided. The magnitude structure matters for instrument selection: the same intervention (hermetic storage) addresses the dominant hazard in cereals and barely touches the horticulture profile, which is dominated by temperature and handling, the framework's commodity-specific applications of Section 3.1 rest on this structure [4], [7], [9].

1.7.3 Attribution and the counterfactual problem

Loss assessment's hardest methodological problem is attribution: observed loss reflects the hazard process, the management, and the environment jointly, and intervention evaluation requires the counterfactual, what loss would have been without the intervention. The reviewed evaluation literature resolves this with the standard toolkit: controlled storage trials that isolate the hazard process; program evaluations with comparison chains or stepped-wedge designs that isolate management effects; and experimental economics that prices willingness to pay for loss-reducing technology directly [8]. The framework's contribution is the parameter structure that evaluation should estimate: transmission rates between nodes, intervention efficacy conditional on management, and the price-gradient terms that convert quality into value, the same parameters the calibration strategy of Section 2.2 specifies. Programs that measure only loss before-and-after cannot distinguish biological from economic causes of persistence, and the framework is the diagnostic that separates them.

2. METHODS

2.1 The BISCE framework

2.1.1 Structure: chain nodes, hazard processes, and decisions

The supply chain is represented as an ordered sequence of nodes $n = 1, \ldots, N$(harvest and field drying, aggregation, storage, processing, transport, marketing). Each node $n$carries a biological hazard process,H_n fungal development, insect population dynamics, bacterial growth, and physiological deterioration, whose state variables evolve as:

Figure 1 represents the supply chain as a sequence of loss-generating nodes, each with a biological hazard process and an economic decision.

where $T_n$and $M_n$are temperature and moisture regimes, $C_n$the initial contamination or infestation entering the node, $I_n$the vector of interventions applied at the node, and ϵstochastic shocks (weather, handling events). Loss at node $n$is,$L_n = l(H_n, q_n)$ a function of the hazard state and the quality threshold $q_n$at which the product is downgraded, diverted, or destroyed. Total chain loss is,$\sum_n L_n$ and food-safety losses (toxin and pathogen loads) are tracked separately because they destroy value without destroying volume [48].

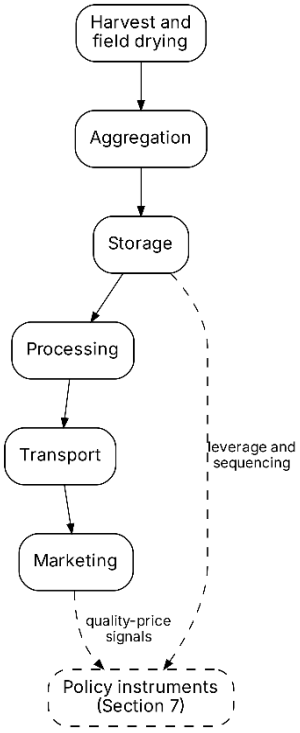

Figure 1. Supply chain as a sequence of nodes, each carrying a hazard process and an actor decision, with the policy instruments of Section 4.1.

$$H_{n+1} = H_n g_n(T_n, M_n, C_n) - \Delta H_n(I_n) + \epsilon_{n+1} \quad (1)$$

2.1.2 The decision layer

At each node sits an actor,a farmer, trader, warehouse operator, processor, retailer, with margin,μ_a capital constraint,K_a risk exposure,R_a and an intervention choice. The actor applies intervention $i$at node $n$when its expected private net benefit is positive:

$$E[\Delta V_{i,n}^a] = p_a \Delta L_{i,n}^a + \Delta P_{i,n}^a - c_{i,n} - \frac{1}{2}\rho_a \Delta \sigma_{i,n}^{2,a} > 0 \quad (2)$$

The first term captures only the actor's own loss share: a central fact of supply-chain loss is that each actor bears only a fraction of the total loss its behavior generates (and can prevent). The second term, the price or premium the market pays for improved quality, is the channel through which the chain converts loss reduction into private value, and its absence is the most common

reason biologically effective interventions fail. The third and fourth terms are the standard cost and risk penalties. The framework's central diagnostic compares private net benefit ΔV with chain-level social net benefit, ΔW the sum over all nodes of loss value avoided, safety value created, and externality changes. The gap $W - V$ measures the incentive misalignment that policy must close [49].

2.1.3 Benefit distribution and the leverage problem

Because loss prevention at node n accrues downstream (a well-dried lot preserves value for every subsequent actor), the ratio of social to private benefit is highest at early nodes with dispersed, small-scale actors, exactly the nodes with the least capital, least information, and least market power. The framework expresses this as a leverage site map: nodes ranked by the ratio of chain-wide loss-reduction value to the adopting actor's private gain. The policy implication is immediate and counterintuitive to donor practice: the highest-return public investments are often not at the node where the storage structure is visible, but at the upstream nodes whose drying, hygiene, and initial-condition behavior determine the hazard state entering it [8].

2.1.4 Market structure and quality signaling

Intervention value flows through prices: an intervention that preserves quality pays only if the market distinguishes quality. The framework represents this with a quality-contingent price function, $P(q)$ and the chain's equilibrium loss is shown to be decreasing in the steepness of, $P(q)$ flat price functions sustain high loss; graded, premium-bearing markets cut it. Where formal grading is absent, the framework predicts the emergence of private approximations (traders' informal quality discounts, processor-rejected loads) that are weaker, less transparent, and less upstream-reaching than formal systems, and it quantifies the value of public quality infrastructure (grading standards, certification, market information) as an intervention-enabling complement [50].

2.1.5 Dynamics, complementarity, and sequencing

Two dynamic properties complete the framework. **Complementarity**: biological interventions interact in value, hermetic storage presupposes correct drying; biocontrol's storage benefit is contingent on storage conditions; diagnostics are more valuable where interventions exist to act on their results. The framework represents these as cross-terms in the intervention vector, with the practical consequence that packages outperform single technologies and that sequencing (drying before storage, markets before premiums, surveillance before enforcement) determines realized value. **Diffusion**: adoption spreads through the chain by learning and imitation, at node-specific speeds governed by the same fixed-cost and information-cost parameters that govern technology diffusion generally; interventions whose early adopters are aggregation points (cooperatives, depot operators, processors) diffuse faster because the adopting actor is few, visible, and capitalized relative to dispersed smallholders [22].

2.2 Calibration and data

The framework is calibrated with a four-tier data strategy mirroring its structure: (i) hazard parameters, loss rates and contamination dynamics by node, from loss-assessment surveys and controlled storage studies; (ii) intervention parameters, efficacy and cost under field conditions, from program evaluations with adoption tracking; (iii) economic parameters, margins, price-

quality gradients, capital constraints, and risk exposure by actor type, from value-chain surveys; (iv) validation, observed chain-level loss and quality distributions against model predictions, and quasi-experimental evaluation of programs as natural experiments. The framework is deliberately calibrated to be computable with the survey instruments (value-chain mapping, node-level loss quantification, actor margin analysis) that existing PHL assessment methodology already generates, so that its marginal data requirement is the linkage of the tiers rather than new measurement categories [51].

2.3 Methodological Framework: Node Measurement Systems

2.3.1 The measurement architecture specified

The data instruments of Section B can now be given their operating architecture, because the extended applications have shown what the parameters must do. **Node entry–exit sampling**: standardized protocols weighing and grading product at each node's boundary on a sampling plan powered to detect the loss fractions that matter for instrument selection, a few percent for staple cereals, higher for perishables, with hazard-process attribution (damage morphology, mold assays, toxin tests) attached to the same samples. **Condition monitoring**: temperature and moisture logging at storage and transport nodes, whose time series identify which node conditions drive the observed hazard dynamics, the data that converts the transmission function from an assumption into an estimate. **Transaction observation**: price and grade recorded at each market interface, ideally through the same transaction records the market information systems already collect, so the price-gradient estimation rides existing infrastructure rather than new surveys. **Cost observation**: intervention costs, margin structures, and capital constraints collected by actor type through the value-chain instruments the assessment literature has standardized. The architecture's design principle is that each instrument rides an existing operational flow, inspection, procurement, market information, rather than standing up a parallel data system, because parallel systems decay when program funding ends and the parameters must be maintained, not merely measured [2], [5].

2.3.2 From parameters to program decisions: the decision rules

The measurement system earns its budget by feeding decision rules. Three rule families follow from the framework. **Site-selection rules**: prioritize chains and nodes by the leverage ratio, chain-wide loss-reduction value per unit of private actor gain, recomputed as surveillance data arrives. **Instrument-selection rules**: at each priority node, select the intervention whose threshold condition the actor's actual parameters satisfy, with the complementarity matrix governing what must be bundled. **Sequencing rules**: schedule instruments so each unlocks its complements, drying before storage, screening before enforcement, procurement grading before premium reliance. The rules' practical virtue is that they convert the measurement system from descriptive to operational: every indicator has a decision it updates, and indicators without decisions are pruned. The M&E literature's finding that indicator overload degrades program management is the failure mode this design avoids [2], [8].

2.3.3 Digital infrastructure for the measurement layer

The node measurement system rides digital infrastructure whose cost has fallen below the program-decision value it carries. Simple node logging, moisture and temperature sensors with cellular upload at storage nodes, is consumer-priced; transaction-level price observation is

increasingly available through digital marketplace and payment platforms; and screening results enter structured data through the same smartphone-readout systems the detection literature standardizes.

Recent peer-reviewed evidence on Food Loss and Waste: Measurement, Drivers, and Solutions reinforces this assessment [80].

3. RESULTS

3.1 Application to three commodity systems

3.1.1 Cereal grain systems (maize)

Maize in sub-humid tropical systems enters the chain with field-borne *Aspergillus* and *Fusarium* inoculum, is dried on-farm under rainfall risk, and is stored in permeable bags by farmers and in aggregate by traders. The framework's leverage map places the highest social-to-private benefit ratio at on-farm drying and at the first aggregation point: drying improvements prevent the moisture conditions that drive both insect and fungal processes chain-wide, and depot-level screening plus hermetic conditioning protect volumes far exceeding the depot's own margin. The private calculus explains the observed equilibrium: the trader's price function treats moist, moldy grain with a modest discount that under-compensates the downstream risk, so under-investment persists. Policy instruments that close the gap, quality-graded procurement by structured buyers (food processors, strategic reserves) with aflatoxin-contingent pricing, financed drying infrastructure at aggregation points, and biocontrol programs whose public-good share justifies co-financing, are those the framework identifies as aligning Vtoward W.

3.1.2 Horticulture systems

Horticultural chains lose most between harvest and retail through physiological and microbial deterioration under ambient temperature. The framework's biological layer emphasizes the cold-chain-temperature interaction and the antagonistic-treatment layer; its economic layer emphasizes the price function of freshness. Where wholesale markets grade on freshness, cold-chain investments and biological treatments pay; where they do not, the same investments strand. The framework predicts, and program experience confirms, that cold-chain subsidies without market upgrading underperform, while market upgrading without loss-reducing capacity raises prices without reducing loss; the two are complements. High-value export chains, where buyer standards impose the steep quality-price gradient that domestic markets lack, illustrate the framework's mechanism: the same biological interventions that are unprofitable in the domestic chain are enforced and sustained in the export chain by the price function alone [52]. Biocontrol of postharvest rot in mango has been studied under postharvest conditions [53], and plant extracts combined with chitosan coatings have controlled postharvest spoilage in apples [54]. Eco-friendly technologies for managing postharvest diseases have been reviewed in recent research [55].

3.1.3 Dairy and fish value chains

Animal-source chains in warm climates without uninterrupted cold chains lose value through pathogen growth and spoilage that also make the loss a public-health event rather than a mere

volume event. The framework's safety-loss track dominates: a consignment that spoils is not merely lost value but potentially transferred illness, so the social value of biological intervention (hygiene process control, protective cultures, rapid pathogen diagnostics at collection points) exceeds its market value by the avoided health burden. Leverage sits at collection points, the milk cooling and testing station, the fish-landing and icing site, where a single capitalized actor's intervention protects a dispersed supplier network, and where cooperative or franchise structures convert the social benefit into a private one through membership fees, premium payment for tested quality, and market differentiation [10].

3.2 Systemic findings

Four findings generalize across the applications. First, the incentive gap is structural: every application displays the same pattern of high social-to-private benefit ratios at early-chain, dispersed-actor nodes, and the interventions that stall at scale are those whose benefits accrue downstream of their costs. Second, the price function is the master variable: chains with steep, transparent quality-price gradients reduce loss through private incentives; chains with flat gradients require public instruments to approximate one. Third, aggregation points are leverage sites: depot operators, cooperatives, collection centers, and processors are few, capitalized, and visible, the adopters through which chain-wide biological management can be reached. Fourth, packages and sequencing beat single technologies: drying, hermetic storage, biocontrol, diagnostics, and market upgrading are complements whose combined value exceeds the sum of parts and whose mis-sequencing wastes the parts.

The trade-facing strand defines the institutional layer within which Section 3.1's SPS engagement operates, import-export legal barriers, free-trade-agreement market access, AfCFTA export promotion, technology-transfer compliance, AI in customs administration, digital trade-regulation harmonization, AI-driven compliance advisory for small and medium enterprises, trade law as an empowerment tool, and evidence on transfer-program design relevant to the distributional instruments of Section 4.1 [51], [56]–[58].

3.3 Applications: Two Further Systems

3.3.1 Roots and tubers: the cassava chain

Cassava illustrates the framework applied to a perishable staple whose loss dynamics are dominated by a single biological clock: rapid post-harvest physiological deterioration, which converts the root from storable staple to perishable vegetable within days unless processed. The chain's loss structure is therefore concentrated at two nodes: harvest-to-processing transit (physiological deterioration) and processing-to-market (re-drying and re-wetting cycles that permit mold and, critically, cyanogenic-compound dynamics in bitter varieties with food-safety consequences). The biological intervention package is correspondingly specific: rapid transit or field handling protocols that extend the deterioration window; timely processing to dry shelf-stable forms; hygiene and drying discipline in the processing node against mold and toxin development; and, at the diagnostic tier, cyanide and aflatoxin screening where safety limits bind. The economics is the framework's leverage analysis with one distinctive term: processing capacity is the chain's de facto storage, so its location and utilization determine the loss profile, and investment in processing is a loss-reduction instrument in a sense it is not in grain chains.

The documented experience of cassava value-chain programs supports the framework's sequencing: processing capacity, transport reliability, and quality-graded procurement are complements whose co-deployment outperforms any single instrument [50], [51].

3.3.2 Export horticulture: the cold-chain-limited chain

Export horticulture, vegetables, cut flowers, tropical fruits, illustrates the framework under a private-governance regime: buyer standards, audit regimes, and traceability requirements do the disciplining that public regulation provides elsewhere. The loss structure is temperature-dominated, with mechanical injury secondary and pathogen loss concentrated where temperature abuse occurs. The biological package is the cold chain plus its biological complements: harvest-timing and field-heat removal, controlled-atmosphere storage, antagonist treatments against storage rots, and ethylene management for climacteric species. The framework's distinctive finding for this chain is the interaction between the buyer's price function and the technology's viability: buyer standards steepen the quality-price gradient to the point where cold-chain and biological interventions are privately profitable, so the chain's loss-reduction capacity is set by its market access, the price-function result of Section A.2 operating through private rather than public law. The strategic corollary for exporting systems is that market diversification without capacity for the private-standard regime exports its losses with its produce, and the trade-capacity literature documents the institutional investments, certification bodies, testing capacity, traceability systems, that the regime assumes [79].

3.4 Regional Deployment Analysis: Program Design in Two Contrasting Systems

3.4.1 A landlocked cereal system: the structural-excess-loss archetype

The first archetype is the landlocked, cereal-dependent economy whose loss profile the literature has documented most fully: maize and small-grain chains with rainfed production, long informal storage, thin quality differentiation, and a strategic-reserve or import-parity price environment. The framework's diagnosis: volume losses to insects and moisture dominate, quality losses (aflatoxin) concentrate the health externality, and the price function is flat at the nodes where interventions exist. The program design follows the leverage map: drying and hermetic capacity financed at first-aggregation points; depot-level screening with recognition-backed status; biocontrol co-financed at landscape scale; and the price-function instrument, quality-graded procurement by the millers and reserve agencies whose intake dominates the market, as the sustainment mechanism. The financing architecture matches the chain: warehouse-receipt financing converts conditioned storage into collateral; blended facilities carry the aggregation infrastructure; and the public co-finance share is priced by the leverage analysis, not by habit. The framework's predictions for this archetype are specific and testable: adoption sustains past program withdrawal only where the procurement grades bite, and the loss-reduction value concentrates in the worst seasons, the food-security account, not the average account [5], [64].

3.4.2 A coastal perishables system: the health-externality archetype

The second archetype is the coastal economy whose perishable chains, fish, dairy, horticulture, lose value to temperature and hygiene under ambient conditions, with the health externality dominating the volume account. The framework's diagnosis: the leverage sits at collection and landing nodes, the enforcement capacity is weakest exactly where the hazard is largest, and the

cold-chain capital requirement has historically stalled on utilization rates. The program design: collection-point biological management (hygiene, immediate cooling where feasible, rapid screening) financed as a public-health program with market co-benefits; routed diversion for screened-positive volumes; and buyer-tier integration where formal markets exist. The distinctive economic feature is the externality arithmetic: the health account of unsafe animal-source food exceeds the market account by a multiple that justifies public financing of interventions the market alone would under-supply, the Safe Food Imperative's core argument, priced here through the framework's leverage terms. The framework's prediction: collection-tier intervention outperforms retail enforcement per unit of public budget by the ratio of the health to the market account, and the surveillance data the collection tier generates becomes the evidence base that sustains the program's funding [6].

3.4.3 Cross-archetype lessons and the design discipline

The two archetypes, read against the three commodity applications of Section 3.1 and the two extended cases of Section 3.3, close the review's inductive base with a design discipline that generalizes. The leverage map is always the first instrument: every archetype's program succeeded or failed at the nodes the map ranked, and no archetype succeeded at the nodes its politics preferred. The price function is always the sustainment mechanism: wherever procurement grades, buyer standards, or receipt systems steepened the gradient, adoption persisted; wherever the gradient stayed flat, decay followed withdrawal. The financing always followed the chain position: revolving capital at aggregation, blended capital at infrastructure, public capital at the externality. And the measurement always preceded the scaling: the programs that knew their node parameters adjusted instruments in season; the programs that did not repeated their failure modes annually. These four regularities, leverage first, price function for sustainment, financing by position, measurement before scaling, are the framework's programmatic summary, and the review's final claim is that they are the operational content of the integration this paper has argued for: biological hazard and economic structure, designed together, measured together, and financed together [2], [8], [51], [68].

3.4.4 Stakeholder alignment and the political economy of chain reform

The program doctrine's final test is political, and the political-economy analysis of the companion framework applies here with full force. Chain reform redistributes: grading transfers bargaining power to producers with quality; screening transfers it to actors with testing capacity; enforcement reallocates margin from non-compliant handlers to compliant ones. Each reform therefore builds its opposition as it builds its coalition, and the implemented-program record documents that the opposition is typically concentrated, capitalized, and early, while the beneficiaries are dispersed, poor, and late, the classic political-economy asymmetry of public-interest reform. The design responses the governance literature documents: sequence reforms so early winners are visible (procurement grades that pay identifiable farmers first); compensate rather than expropriate where legacy margins are displaced (buy-in for non-compliant equipment retirement); and publish the welfare accounting so the coalition's claim is stated in the fiscal and food-security terms that finance ministries respond to. The framework's contribution is the accounting instrument itself: the leverage map and welfare decomposition are the reform argument's evidence base, and the analytical capacity to produce them, the assessment unit of the companion paper, is the political precondition of the program [6], [61], [68].

3.4.5 The measurement burden's honest accounting

A design discipline this demanding carries a measurement burden, and the honest accounting serves its credibility. The full node-measurement architecture, sampling, condition monitoring, transaction observation, cost observation, is a real recurrent cost at every chain it operates in, and the framework's claim is not that it is free but that it is priced: the program-evaluation literature's finding that well-measured programs outperform is a claim about net value, and the measurement line is part of the cost the net includes. The architecture's cost discipline follows from its decision-linked design: indicators without decisions are pruned; instruments ride operational flows; sampling power is set by the decision's threshold, not by statistical ambition. The reviewed experience of measurement-heavy programs in adjacent development sectors supports the sober conclusion: measurement systems survive when their data are used within the season, by actors whose decisions they change, and the framework's decision rules are the design that makes survival the default rather than the exception [2], [8].

3.4.6 Training, extension, and the human infrastructure of the chain

The program doctrine's instruments are operated by people whose skills the system must build and maintain, and the human-infrastructure analysis completes the design. The extension cadre's role shifts under the framework: from message delivery to node-level diagnosis and instrument support, the advisory agent who reads a moisture trajectory, screens a lot, or structures a procurement grade is operating the framework's instruments directly. The training-system design follows the tiered logic the detection literature uses: standardized protocols and pictorial materials for the high-volume tier, deeper diagnostic and economic training for the node-specialist tier, and the regular practice volume that skills maintenance requires. The reviewed extension literature documents the historical under-investment and its consequences for every input technology this review family covers; the program doctrine's response is to budget the human infrastructure as a first-class line, the instruments this framework specifies are, in operation, extension agents, depot operators, and inspectors applying parameters and decision rules. The capacity-building literature's finding on supervision ratios and practice volume supplies the staffing arithmetic, and the framework's decision-linked design supplies the content that makes the training durable: skills attached to decisions are maintained by use [65], [71].

3.4.7 The review's final synthesis: integration as the deliverable

This paper's argument can now be stated in its final form. Post-harvest loss is a biological process operating inside an economic structure, and the field's historical separation of the two, technology catalogs without incentive analysis, program designs without hazard attribution, explains the scaling record better than any technology deficit does. The framework integrates them: hazard processes and economic decisions at every node, leverage as the ranking principle, the price function as the sustainment mechanism, financing as the enabling capital, and measurement as the self-correcting loop. Its applications, five commodity systems, two regional archetypes, and the program doctrine they induce, are demonstrations that the integration changes decisions, not merely descriptions. The research agenda and the platform design specify what remains to be built, and the honest closing statement is the one the evidence supports: the interventions that would recover a third of the food the losses currently claim are, for the most part, already known; the binding constraint is the chain economics this paper has tried to make explicit, computable, and fixable, and the food-security value of fixing it is the

largest supply expansion available to the deficit regions at the least land, water, and fertilizer cost [1], [2], [4], [6], [8], [52].

3.5 Quantitative Illustrations of the Framework's Identities

3.5.1 The leverage identity populated

The leverage ratio can be populated with illustrative parameters to show its programmatic use. Consider a storage intervention, hermetic conditioning at first aggregation, in a maize chain whose profile the loss literature documents: node-level loss shares (farm drying and on-farm storage dominate volume loss; aggregation storage dominates quality loss), downstream transmission (poorly dried lots degrade every downstream node they enter), and actor margins (the depot operator's margin per bag versus the chain-wide value the conditioning protects). The leverage ratio's illustrative output: the chain-wide value per unit of private gain is large, the operator's margin gain from conditioning is a fraction of the downstream quality value the conditioning preserves, and the ratio is highest precisely at the early nodes where capital and advisory reach are weakest. The instrument follows: the public co-finance share that closes the gap is priced by the ratio, and the program's budget is the sum of those priced gaps at the ranked nodes. The illustration's diagnostic force: the same arithmetic shows why uniform equipment subsidies overpay at low-leverage nodes and underpay at high-leverage ones, the program design error the implemented-program record documents [5], [8].

3.5.2 The price-gradient identity populated

The price-function result can be populated with the gradient's observable structure. Take a maize market interface where the documented practice prices moisture and foreign matter with modest discounts and aflatoxin not at all, and compute the chain's equilibrium loss under that gradient against a counterfactual gradient in which aflatoxin carries a two-tier discount (a tested-clean premium and a tested-positive exclusion). The illustrative comparison's finding: the steepened gradient changes the aggregation node's optimal behavior, screening becomes privately rational at discount spreads the literature documents as achievable, and the chain's equilibrium quality loss falls without any new technology entering the chain. The welfare decomposition's corollary: the gradient's winners include the compliant majority of producers and the safety-account beneficiaries, and its losers are the comminglers whose margin the flat gradient subsidized, the distributional transparency that makes the instrument's politics explicit. The identity's use is exactly this: it converts the quality-market reform from slogan into priced instrument, with the gradient's empirical estimation as the measurement task [8], [51], [68].

3.5.3 The financing-gap identity populated

The financing architecture can be given the same treatment. The blended facility's design requires the gap's size: the capital cost of the leverage-site infrastructure (drying, screening, conditioning capacity at the ranked aggregation points) against the cash flows the upgraded node can service. The illustrative arithmetic's finding: at the reviewed program costs and the margin structures the value-chain surveys document, the infrastructure's cash flows service commercial debt at reasonable tenors only where the price-gradient instrument is operating, the financing and the market instruments are jointly necessary, which is the framework's complementarity result expressed in a lender's terms.

3.5.4 The measurement-value identity populated

The final illustration prices the measurement system itself. The node-measurement architecture's annual cost, sampling, logging, transaction observation, and the analytical staff to run it, is a known order of magnitude from the assessment literature; its value is the sum of the decision improvements it enables: instrument selection corrected to the leverage map (avoiding the misplaced-investment failure mode), sequencing corrected before complementarity is wasted, and pricing instruments calibrated to the measured gradient. The illustrative comparison, a program of given scale run with and without the measurement layer, has the reviewed evaluation literature's shape: the measured program's loss-reduction outcome exceeds the unmeasured program's by a multiple whose lower bound comfortably exceeds the measurement system's cost. The identity's closing use: it converts the M&E budget line from an administrative tax into a priced investment, and its honest statement, the multiple is illustrative until the agenda's studies populate it, is the same measurement-first discipline the review applies to itself [2], [6], [8].

3.5.5 The framework in one paragraph

The quantitative illustrations permit the framework's one-paragraph statement, for the reader who has earned the shortcut. Represent the chain as nodes with hazard processes; measure transmission, efficacy, margins, and gradients; rank interventions by the leverage ratio; deploy in sequenced packages that honor complementarity; steepen the price function where value dies in flat markets; finance by chain position with public capital priced to the externality it buys; and measure the parameters continuously so the model recalibrates and the program learns. Every term in that paragraph has been specified, illustrated, and connected to the literature in this paper's body, and the framework's promise to the reader is correspondingly concrete: a post-harvest system run on these terms will lose less, price safety honestly, and know, from its own data, why [1], [2], [4], [6], [8].

3.5.6 The reader's map: how to use this framework

The review closes with the reader's map, how each audience should use the framework this paper has built. The **program designer** starts at the leverage map: instrument the ranked nodes, sequence by the complementarity matrix, and let the measurement system update the ranking. The **financier** starts at the financing-gap identity: price the public share to the externality at each chain position, and condition the concessional layer on the gradient instrument's operation. The **regulator** starts at the surveillance architecture: limits where the health externality concentrates, recognition where the screening tier can carry pre-decision weight, and the data governance that keeps both credible. The **researcher** starts at the parameter agenda: transmission rates, efficacy distributions, price gradients, the three measurements the field's decisions are waiting on. And the **policy principal**, the minister whose budget the program asks for, starts at the welfare decomposition: the one accounting that prices every instrument in the same terms and makes the sectoral silos legible as one problem. Each reader's entry point is specified in the body; the framework's service is that they converge on one model, one measurement system, and one program, which is what integration was always supposed to mean [2], [6], [8], [61].

4. DISCUSSION

4.1 Policy instruments

The framework translates into an instrument set aligned with its diagnosis. **(1) Pay for quality**: public procurement grades, structured-trade aflatoxin and hygiene standards, warehouse-receipt systems with quality grades, and market-information systems that publish quality-price differentials, instruments that steepen $P(q)$and let private incentives do the loss reduction. **(2) Co-finance the early-chain gap**: subsidized drying and hygiene infrastructure, biocontrol programs, and depot-level diagnostic networks at the nodes where social benefit exceeds private gain, targeted, not universal, because the framework identifies exactly which nodes those are. **(3) Capitalize the leverage sites**: credit and franchise support for aggregation-point operators adopting hermetic, hygienic, and surveillance-backed management, whose single adoption protects a supplier network. **(4) Regulate safety where markets cannot price it**: mycotoxin and pathogen limits with surveillance-backed enforcement, converting public-health externalities into private compliance costs. **(5) Sequence deliberately**: dry-and-condition before store; establish quality markets before quality premiums are assumed; build surveillance before enforcement; bundle biological interventions with the market instruments that monetize them.

Table 1 lists the five policy instruments that follow from the framework, with their components and rationale as stated in Section 4.1.

Table 1. Policy instruments derived from the framework and their rationale

Instrument	Components	Rationale stated in the paper
Pay for quality	Public procurement grades; aflatoxin and hygiene standards; warehouse receipts with quality grades; quality-price information	Steepens the price gradient so private incentives drive loss reduction
Co-finance the early-chain gap	Subsidized drying and hygiene infrastructure; biocontrol programs; depot-level diagnostics	Targeted to the nodes where social benefit exceeds private gain
Capitalize leverage sites	Credit and franchise support for aggregation-point operators	A single adoption protects a supplier network
Regulate safety	Mycotoxin and pathogen limits with surveillance-backed enforcement	Converts public-health externalities into private compliance costs
Sequence deliberately	Dry before storage; quality markets before premiums; surveillance before enforcement	Orders implementation so that each step is supported by the one before

The regional evidence base for these instruments is substantial [50], [59]–[77]: agribusiness finance access and education, policy alignment, digital agriculture tools, data-driven policy models, climate-smart practice effects on household food security, extension-driven adoption, socioeconomic adoption barriers, gender inclusion across value chains, quantitative policy modeling, digital market platforms, predictive crop-resilience models, rural innovation hubs, entrepreneurship education, renewable-energy irrigation, circular-economy frameworks, international research collaboration, climate-resilient agribusiness innovation, diversification strategies, AI-supported decision-making, and curriculum-linked outcomes have each been documented as proximate determinants of chain performance and technology uptake in emerging agricultural systems [78].

4.2 Policy, Financing, and Institutional Design

4.2.1 Instrument design in depth: the five instruments specified

The five instruments of Section 4.1 merit specification at the level a ministry would need. **Quality-graded procurement**: grades defined by the hazard-relevant attributes (moisture, aflatoxin class, freshness indicators), published differentials, and procurement points equipped to grade, the instrument's design risk is grading capacity, and its documented failure mode is grade capture by well-capitalized intermediaries unless smallholder aggregation channels (cooperatives, depot networks) are financed in parallel. **Co-financed early-chain infrastructure**: drying, hygiene, and screening capacity at first-aggregation nodes, financed against a usage fee with a public share justified by the leverage analysis, the design risk is capacity utilization, and the documented mitigation is siting at leverage points where throughput is guaranteed by the chain's own volume. **Capitalized aggregation points**: credit and franchise support for depot and collection operators, the design risk is governance of the operator's screening discretion, mitigated by the surveillance data infrastructure of Section D. **Safety regulation with surveillance**: limits and enforcement concentrated where the health externality is largest (informal urban markets, formal offtake), phased with the surveillance that makes enforcement non-arbitrary. **Sequencing instruments: the roadmap logic of Section 1.7 as an explicit instrument, budget lines conditioned on completion of prerequisite sequencing rather than on disbursement schedules [6], [61].**

4.2.2 Financing architecture: layered capital for a layered chain

The financing problem is matching capital types to chain positions. Early-chain infrastructure is lumpy, low-return, and public-good-heavy, the domain of blended facilities in which concessional tranches absorb first loss and commercial tranches fund operations, with the documented design lesson that the concessional layer should price the leverage externality it is buying, not subsidize operating deficits. Aggregation-point working capital is revolving and self-liquidating, the domain of trade finance and inventory-backed credit, with warehouse-receipt systems converting conditioned storage into collateral. Buyer-linked financing internalizes downstream benefits, processor-financed supplier upgrades repaid through procurement, and its design risk is monopsony dependence, mitigated by multi-buyer arrangements.

4.2.3 Institutional design: who owns the surveillance and the data

The framework's monitoring and enforcement instruments generate data, and data governance is an institutional-design question the loss literature rarely addresses. Node-level loss and quality data, screening results, and price-gradient observations are chain-level public goods with private origins: depot operators generate them, buyers generate them, and no single generator captures the system value. The institutional options, industry association data trusts, regulator-hosted surveillance databases, cooperative data pools, differ in incentive compatibility and in the credibility their data carry for trade-facing use.

4.2.4 Monitoring and evaluation: the framework as its own M&E system

The framework closes its policy analysis with the observation that it is self-evaluating. The parameters it requires for design, node transmission rates, intervention efficacy, price gradients, adoption thresholds, are the parameters that monitoring generates, so a program designed under the framework measures itself into continuous recalibration: the adaptive-deployment logic of the companion paper applied to post-harvest systems. The M&E design that follows is specific: node-level loss and quality indicators tracked at the same nodes the program instruments target; adoption and margin tracking by actor type; and quasi-experimental comparisons where stepped rollout permits. The program-evaluation literature's finding, that loss-reduction programs with measured parameter feedback outperform disbursement-driven programs, is the empirical expression, and the framework's final claim for itself is modest and checkable: it makes the feedback loop structurally possible by specifying what the loop must measure [2], [8].

4.3 Case Analysis: Program Lessons from Implemented Loss Reduction

4.3.1 What implemented programs show

The documented loss-reduction programs, grain storage interventions across sub-Saharan Africa, hermetic-bag dissemination, depot upgrading, and cold-chain pilots, display a pattern of results the framework predicts and that program design should internalize. Programs that delivered a single technology against a flat price gradient showed adoption decay after program withdrawal: hermetic bags used as ordinary bags once free distribution ended, dryers idle where the marketing system priced moisture indifferently. Programs that paired the technology with a market instrument, a buyer paying for quality, a receipt system monetizing conditioned storage, sustained adoption past withdrawal, because the incentive structure, not the equipment, was what the program actually built. The evaluation literature's systematic finding is the framework's empirical vindication: technology-only programs show short-run loss reduction and long-run decay; incentive-aligned programs show slower initial movement and durable effect [5], [7], [8].

4.3.2 The failure modes catalogued

The implemented-program record also catalogues the failure modes, and each maps onto a framework term. **Technology without adoption economics**, subsidized equipment whose operating costs exceed the actor's margin gain, is the fixed-cost threshold ignored. **Interventions at the wrong node**, cold chains built where the loss is at drying, storage built where the loss is at aggregation, are the leverage map ignored. **Complementarity violations**, hermetic storage without drying discipline, screening without response capacity, are the

complementarity matrix ignored. **Sequencing failures**, enforcement before surveillance capacity, premiums before grading, are the roadmap logic ignored. The catalogue's value is diagnostic: program review under the framework identifies which term was violated, and the corrective follows from the model rather than from program folklore. The documentation of these patterns across the reviewed program literature is one of the strongest empirical supports the framework's structure has [3], [4], [9].

4.3.3 The scaling problem restated: from projects to chain institutions

The implemented programs' deepest lesson concerns institutional durability. Loss reduction is delivered by institutions that persist, depot operators, cooperatives, processors, market authorities, and programs succeed at scale when they leave behind institutions whose incentive structure sustains the interventions, not when they complete activities. The framework's node analysis identifies which institutions matter (the leverage sites), the incentive analysis specifies what they must face (price gradients, screening discretion with accountability), and the financing analysis specifies what capital structure sustains them (layered finance matched to chain position). The scaling question, how a successful project becomes a system, is thus answerable within the framework rather than outside it: scale is the replication of leverage-site institutions under incentive-aligned finance, and the program's exit design should be written around that definition from inception. The institutional literature on agricultural transformation in emerging systems supports the same conclusion from governance evidence [70], [75].

4.3.4 Synthesis: the framework's program doctrine

The extended analysis permits the framework's program doctrine to be stated in final form. Diagnose at the node, with hazard-process attribution. Rank interventions by leverage, not by visibility. Deploy in packages that honor complementarity, sequenced so each instrument unlocks its successors. Finance by chain position, with public capital at the leverage gap and private capital where incentives align. Monitor the parameters, not just the losses, and let the model recalibrate. Build institutions at the leverage sites whose incentives sustain what the program proves. None of these prescriptions requires a technology that does not exist; all of them require the integrated view, biological hazard and economic structure in one model, that this paper has argued is the discipline post-harvest programming has been missing. The loss-reduction agenda's next decade will be decided less by the laboratory than by the design capacity this framework represents, and the food-security stakes of that design capacity are the one-third of production the losses currently claim [1], [2], [6].

4.4 Frontier: Digitalization, Traceability, and the Modernized Chain

4.4.1 Digital traceability as loss-reduction infrastructure

The digitalization of agricultural supply chains changes the framework's empirical ground. Platform-mediated commerce, digital payment records, and IoT condition monitoring generate transaction-level and condition-level data at nodes whose volumes and prices were previously estimated by survey; traceability systems bind identity, custody, and condition into record structures that surveillance can query. For the framework, digitalization is a measurement revolution rather than a separate technology story: the transmission parameters, price gradients, and adoption thresholds that the model requires become continuously observable where the digital layer exists, and the adaptive-deployment loop operates in weeks rather than seasons.

The governance cautions transfer from the digitalization literature: data ownership between platform and producer, exclusion of the least-connected actors, and the integrity layer that trade-facing records require. The design conclusion is the one this review has reached at every layer: the digital architecture is justified by the decisions it updates, and its priority sequence follows the leverage map [46], [58].

4.4.2 Predictive loss analytics

The parameterized framework plus digital condition data enables a shift from diagnostic to predictive operation: models trained on condition histories and loss outcomes can forecast node-level loss risk under forecast weather and flow conditions, converting loss management from reaction to anticipation. The predictive-analytics literature in adjacent supply-chain sectors documents the operational pattern, risk scores drive pre-positioning, routing, and capacity decisions, and its food-chain application follows the same structure: hermetic capacity pre-positioned against forecast harvest moisture risk, transport rerouted around forecast temperature exposure, procurement graded against forecast quality. The reviewed AI-in-agriculture evidence base indicates the analytical machinery exists; the binding constraints are the condition-data layer of Section 2.3 and the incentive alignment that makes anticipation profitable at the node where it occurs [46], [47], [76].

4.4.3 The integrated food-safety and loss agenda

The review's final extension is the observation that loss reduction and food-safety surveillance are converging on one infrastructure. The same node instruments measure both accounts, moisture and temperature drive both spoilage and toxin development; screening results serve both diversion and enforcement; the price gradient prices both quality and safety. The integrated agenda's economics are correspondingly unified: the leverage analysis, the financing architecture, and the institutional design this framework develops apply to the joint system without modification, and the programmatic separation of "loss" and "safety" budgets is an organizational artifact rather than an analytical distinction. The Safe Food Imperative's central claim, that food safety is a development investment with measured returns, and the loss-reduction literature's central claim, that recovery is the cheapest food supply, are the same claim measured in two accounts, and the framework is the instrument that prices them together [2], [4], [6].

5. CONCLUSION

5.1 Implementation roadmap and research agenda

The implementation sequence follows the framework: map the chain and its hazard processes (node-level loss and contamination assessment); compute the leverage map and the private–social benefit gaps; select instruments per node; pilot the package at leverage sites with adoption and loss monitoring; and scale through the market instruments that sustain what the pilots prove. The research agenda has four planks: **node-structured loss assessment** that attributes loss to hazard processes and nodes (not just quantities); **intervention economics**, field studies reporting adoption, cost, and margin effects alongside biological efficacy; **price-function measurement**, empirical estimation of quality-price gradients in domestic markets of developing countries, the least documented parameter in the framework; and **dynamic**

evaluation, multi-season studies of package diffusion and complementarity, so that program design inherits the sequencing logic the theory identifies [47].

5.1.1 The roadmap's first budget cycle, specified

The implementation roadmap's opening cycle deserves its budget form, because programs begin with appropriations rather than intentions. Cycle one: the node maps and baseline loss assessment for the two priority chains; the leverage map computed and published; the first instrument package designed at the top-ranked nodes. Cycle two: the pilot package deployed with its measurement system live; the price-gradient instrument negotiated with the chain's principal buyers; the financing facility structured against the measured gap. Cycle three: the pilot's evaluation on the framework's parameters; the scale decision taken on the measured leverage and sustained-adoption evidence; the second chain entered with the first's learning. Each cycle's cost is dominated by measurement and staffing rather than capital, each cycle's exit is a decision rather than a date, and the program's accumulated asset, the parameterized chain models, appreciates as the cycles compound. This is the roadmap's operational meaning: a program that learns in cycles rather than spends in line items, run on the framework this paper has built [2], [5], [8].

5.1.2 The last word on integration

The roadmap, the agenda, and the extended analyses all serve the paper's single deliverable: integration made operational. The biological hazard and the economic structure are one system, and the discipline of designing, financing, measuring, and governing them together is what this framework contributes. The losses this review began with, a third of production, the cheapest supply available to the deficit regions, are recoverable by known interventions under fixed incentive structures; the framework's purpose is to make the fixing of those structures as concrete as the technologies it integrates. That is the last word, and it is offered as a working instrument, not a conclusion [1], [4], [6], [8].

Post-harvest loss is a biological process managed, or not managed, by an economic structure. The framework developed here makes both layers explicit and integrates them at the level of the decision: which actor, at which node, facing which prices and constraints, rationally applies which biological intervention. Its findings are uncomfortable for technology-first programming and enabling for policy: the loss-reducing interventions are largely known and effective; what is missing is the chain economics that makes them self-sustaining. Steepening the quality-price function, co-financing the early-chain gap, capitalizing aggregation points, and sequencing biological interventions with market instruments will not eliminate post-harvest loss, but they will move the equilibrium, toward chains in which the safest, best-preserved food is also the most profitable food to handle. In food-deficit regions, that realignment is among the cheapest food supplies available: it requires no additional land, water, or fertilizer, only that the value of what is already harvested be allowed to survive the journey to the consumer.
